Key words: hypobaric hypoxia, high altitude, metabolic cost

Abstract

Many papers showed that long-lasting exposure to hypobaric hypoxia changed the metabolic cost of work and substrate contribution, elevating exercise energy expenditure and carbohydrates utilization. Only few of them have shown how long this adaptive changes are maintained. The aim of the study was to assess the impact of prolonged sojourn at high altitude on the physiological cost of sub-maximal work performed at the sea level.

Eight members of two high altitude expeditions (Lenin Peak 7,134 m a.s.l. and Somoni Peak 7,495 m a.s.l.), 7 males and 1 female, mean age 26 (±4.1) years, volunteered for this study. Aerobic performance was measured by a direct method (breath-by-breath) using an expiratory gas analyser (Oxycon Pro, Jaeger) with an incremental exercise test till exhaustion. The sea level examinations were performed 7 days before the expedition (BEx) and 7 days after (AEx) the last day at over 2,500 m a.s.l. Participants spent 32 (±3) days over 2,500 m a.s.l. at the mean altitude of 4,712 m a.s.l. (±499 m).

Prolonged sojourn at high altitude has changed the ventilatory parameters of sub-maximal work measured at the sea level. The sojourn resulted in an increase in the ventilatory volume (tidal volume, minute ventilation and breath frequency) during the sub-maximal work performed with the same workload. However, the respiratory exchange ratio remained at a high level compared to the baseline.

We suggest that the adaptive changes introduced during the sojourn remain at the sea level and cause increased carbohydrate metabolism.

Background

Many papers showed that chronic exposure to hypobaric hypoxia changed the metabolic cost of work [1] and substrate contribution [2] during efforts performed at the sea level, elevating exercise energy expenditure and carbohydrates utilization [3,4]. Holloway et al. [5] postulated that changes in cardiac high-energy phosphate metabolism may underlie the myocardial dysfunction caused by hypobaric hypoxia. Cardiac response to hypobaric hypoxia resulted in persistent changes in cardiac mass, function, and energy metabolism after trekking to Mt. Everest Base Camp. According to Esposito et al. [6], theoretical models of VO2max limitation seem to contradict the lack of VO2max increase in hypoxia, suggesting a possible role of increased ventilation-perfusion mismatch. This may also affect the ability to perform physical exercise after returning to the sea level.

Hypobaric hypoxia affects cerebrovascular responses to incremental exercise and results in cerebral deoxygenation at maximal intensity. Cerebral oxygenation appears to be an important variable influencing fatigue under hypobaric hypoxia, since the reversal of cerebral deoxygenation at maximal exertion was associated with increased performance [7].

Functional analyses revealed positive effects on VO2max (when measured at altitude) on the maximal power output and on lean body mass. In addition to the positive effects of hypoxia training on athletic performance, there is some recent indication that hypoxia training has a positive effect on the risk factors for cardiovascular diseases [8].

Some authors suggest that hypobaric hypoxia does not influence adaptation changes in a statistically significant way while performing sub-maximal efforts [9,10]. Other authors write that the adaptations abilities could significantly change during such efforts [11,12].

Due to this fact, the aim of the study was to assess the impact of a prolonged sojourn at high altitude on the physiological cost of sub-maximal work performed at the sea level.

Material and Methods

Subjects

Eight members of high altitude expeditions to Lenin Peak 7,134 m a.s.l. and Somoni Peak 7,495m a.s.l., 7 males and 1 female, mean age 26 (±4.1) years, volunteered for this study. Physical characteristics of the examined group (mean ± SD) are shown in Table 1. The sea level examinations were performed 7 days before the expedition (BEx) and 7 days after (AEx) the last day at over 2,500m a.s.l. Participants spent 32 (±3) days at over 2,500m a.s.l. at the mean altitude of 4,712m a.s.l. (±499m) (Fig. 1).

![Fig. 1. Study design of high altitude expeditions (Lenin Peak 7,134m a.s.l. and Somoni Peak 7,495m a.s.l.)](image-url)
Considering a similar character of the two expeditions – siege mountaineering expedition for two 7,000m peaks, altitudes of the base camps and average periods of altitude sojourn, the two groups of alpinists were analysed together.

All volunteers gave informed consent to participate in the study which was approved by the Medical University of Gdansk Regional Ethics Committee.

**Anthropometric measurements**

Body mass (BM) and body composition were estimated using a bioelectrical impedance floor scale (TBF-300 Body Fat Monitor/Scale Analyzer, Tanita, Japan) calibrated in accordance with the manufacturer’s guidelines prior to each test session. One hour following a light breakfast, participants voided their bladders and bowels and, clad only in briefs, underwent duplicate measures in the standing position recommended by the manufacturer’s guidelines. The following parameters were assessed: body mass [kg]; (FAT) – fat mass – [kg] and [%]; (FFM) – fat free mass – [kg]; (TBW) – total body water – [kg]; (BMI) – body mass index – [kg·m⁻²] and also (BMR) – basic metabolic rate – [kcal·24h⁻¹]. All results are presented in Table 1.

Sub-maximal exercise and VO₂max test was performed on a cycloergometer ER900 (Jaeger-Viasys, Germany). This test started at 2 min of resting phase in the seating position, and then turned to 6 min test phase at the power output of 1.5 W·kg⁻¹ with a pedalling rate of 50 rev·min⁻¹; the participants began cycling at workloads increased by 25 W · min⁻¹ until volitional exhaustion. During the test the following parameters were continuously monitored: (VO₂) – oxygen uptake – [mL·kg⁻¹·min⁻¹], [L·min⁻¹]; (VCO₂) – carbon dioxide excretion – [mL·kg⁻¹·min⁻¹], [L·min⁻¹]; (RER) – respiratory exchange ratio; (VE) – minute ventilation – [L·min⁻¹]; (VT) – tidal volume [L]; (BF) – breath frequency [rpm]; (HR) – heart rate [bpm]; an expiratory gas analyser Oxycon Pro of Jaeger and computer software Breath-by-Breath were used.

**Statistical analysis**

Statistical analyses were performed using STATISTICA software 7.0 (StatSoft, USA). The differences between results of physical performance and body composition at the sea level before and after the expeditions were analyzed using Student’s t-test. The level of statistical significance (p) was set at 0.05.

Results

Seven days after a high altitude expedition (32 days at over 2,500m a.s.l.) we observed statistically significant (p<0.005) differences of time (vs before the expedition) in some cardio-respiratory parameters. The obtained data showed a significant increase (p<0.05) in mean values of the heart rate – HR_{stst} [bpm] (124±16 vs 130±11) and minute ventilation – VE_{stst} [L min^{-1}] (38.2±6.6 vs 48.1±8.1) during sub-maximal effort, for the pre- and post-expedition measurements respectively. Figures 2 and 3 present these differences.

We also observed an increase in tidal volume – V_{Tstst} [L] (1.99±0.61 vs 2.14±0.46) and breath frequency – BF_{stst} [1 min^{-1}] (21±7 – 23±5), but this increase was statistically insignificant. Figures 4 and 5 present these variables.

Additionally, as shown in Figures 6 and 7, there were statistically significant changes in the respiratory exchange ratio – RER_{stst} (0.87±0.04 vs 1.02±0.08) and carbon dioxide production – VCO2_{stst} [mL.min^{-1}] (1459.6±191.5 vs 1728.0±323), which may indicate an increased use of carbohydrates and an increase in the physiological cost of work. There are no similar significant differences in oxygen consumption – VO2_{stst} [mL.min^{-1}] (1676.6±170.6 vs 1709.5±327.8).
The aim of the present study was to assess the impact of a prolonged sojourn at high altitude on the metabolic cost of sub-maximal work performed at the sea level. It was demonstrated that high altitude expeditions (32 days in the mountains at over 2,500m a.s.l. on the mean altitude of 4,712m a.s.l.) have an impact on changes in adaptations of sub-maximal work performed at the sea level.

In our study the specific parameter of a human’s aerobic capacity VO₂max decreased but not to statistically significant degree (Tab 1). This is confirmed by other authors [11,13]. Therefore, it appears that repeated short-term exposures to hypoxia during intense physical training do not significantly contribute to the mechanisms responsible for the improvements in aerobic performance observed at the sea level.

After high altitude expeditions we observed a reduction in the total body weight in our tested subjects. This happened at the expense of a statistically significant decrease in FAT (Tab. 1).

The obtained data showed a statistically significant increase in the heart rate during sub-maximal effort (Fig. 2). This might have occurred as a result of changes in pressure in the heart. According to Holloway et al. [5], within 4 days of return from 17-day trekking to Mt. Everest Base Camp (5,300m) the total body weight in the tested people had fallen by 3%, but left ventricular mass, adjusted for changes in body surface area, had disproportionately decreased by 11% (p<0.05). Acute hypoxia in spontaneously breathing anaesthetized animals caused increases in

**Discussion**

The aim of the present study was to assess the impact of a prolonged sojourn at high altitude on the metabolic cost of sub-maximal work performed at the sea level.

It was demonstrated that high altitude expeditions (32 days in the mountains at over 2,500m a.s.l. on the mean altitude of 4,712m a.s.l.) have an impact on changes in adaptations of sub-maximal work performed at the sea level.

In our study the specific parameter of a human’s aerobic capacity VO₂max decreased but not to statistically significant degree (Tab 1). This is confirmed by other authors [11,13]. Therefore, it appears that repeated short-term exposures to hypoxia during intense physical training do not significantly contribute to the mechanisms responsible for the improvements in aerobic performance observed at the sea level.

After high altitude expeditions we observed a reduction in the total body weight in our tested subjects. This happened at the expense of a statistically significant decrease in FAT (Tab. 1).

The obtained data showed a statistically significant increase in the heart rate during sub-maximal effort (Fig. 2). This might have occurred as a result of changes in pressure in the heart. According to Holloway et al. [5], within 4 days of return from 17-day trekking to Mt. Everest Base Camp (5,300m) the total body weight in the tested people had fallen by 3%, but left ventricular mass, adjusted for changes in body surface area, had disproportionately decreased by 11% (p<0.05). Acute hypoxia in spontaneously breathing anaesthetized animals caused increases in
sympathetic nerve activity, increased release of catecholamines, increases in the heart rate and regional vasoconstriction [14,15]. However, the effects of hypoxia on the human sympathetic nervous system are more difficult to determine, and often indirect methods of assessment have been employed.

A sojourn at high altitudes stimulates incremental physiological cost of work in respiratory muscles. Nervous and chemical regulation of breath should decrease ventilatory parameters after returning to the sea level [16,17], contrary to what has been observed. This is determined by a statistically significant increase in minute ventilation (Fig. 3) during sub-maximal effort after 7 days of high altitude expeditions. Tidal volume (Fig. 4) and breath frequency (Fig. 5) increase, but in a statistically insignificant way.

At the same time, many authors suggest that growth factors such as HIF-1α and TNF-α lead to increased carbohydrates metabolism [8, 18]. A higher level of RER (due to an increase in the value of carbon dioxide and equal to oxygen uptake) after mountain trekking in our participants suggested the retained increased carbohydrate metabolism (Fig. 6).

Conclusions

Prolonged sojourn at high altitude changed the ventilatory parameters of sub-maximal work measured at the sea level. However, the respiratory exchange ratio remained at the high level according to the baseline. We suggest that the adaptive changes introduced during the sojourn remain at the sea level and cause increased carbohydrate metabolism and elevated total physiological cost of work.

Conflict of interest

There are no conflicts of interest to be reported by the authors, as there are no professional relationships with companies or manufacturers who will benefit from the results of the present study.
